Does the “DCMF” give the IMF?

What, really, is a “dense core?”

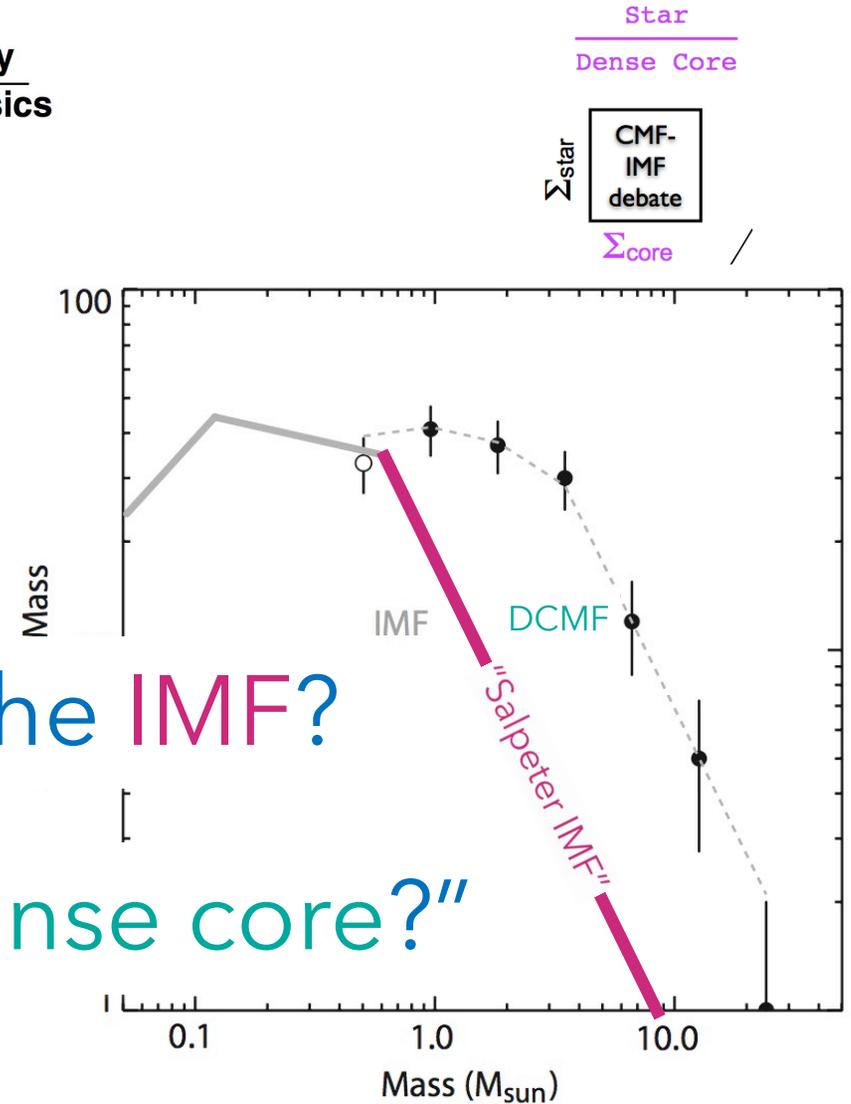

Fig. 2. Mass function of dense molecular cores plotted as filled circles with error bars. The grey line is the stellar IMF for the Trapezium cluster (Muench et al. 2002). The dashed grey line represents the stellar IMF in binned form matching the resolution of the data and shifted to higher masses by about a factor of 4. The dense core mass function is similar in shape to the stellar IMF function, apart from a uniform star formation efficiency factor.

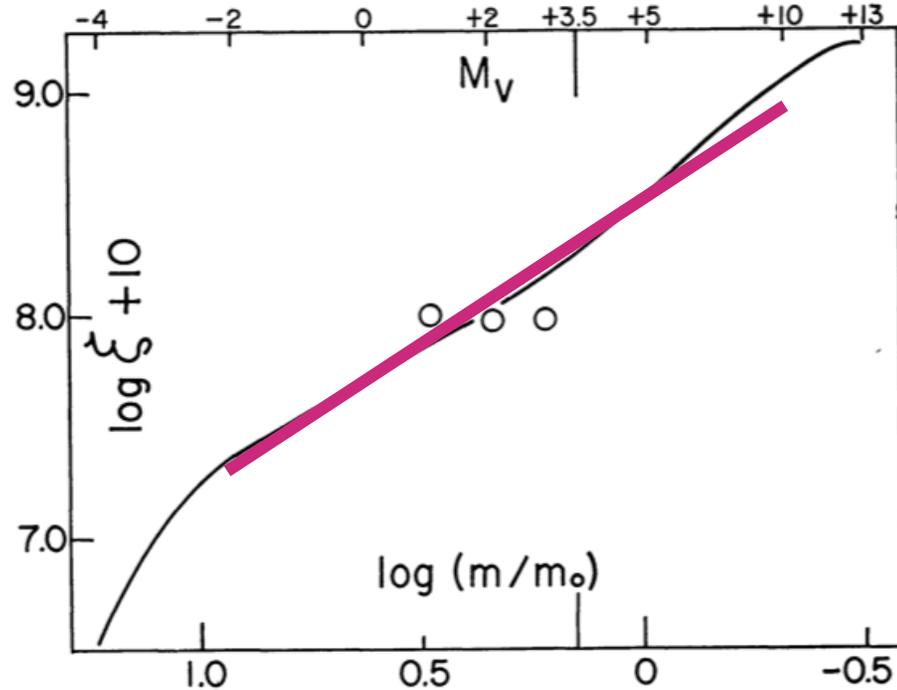

FIG. 2.—The logarithm of the “original mass function,” ξ , plotted against the mass, \mathcal{M} , in solar units.

IV. DISCUSSION

Figure 2 and Table 2 show that the “original” mass and luminosity functions ξ and ψ are, in fact, fairly smoothly varying functions without any very rapid change of slope. For $\log (\mathcal{M}/\mathcal{M}_{\odot})$ between -0.4 and $+1.0$, ξ is given reasonably well by the approximation

$$\xi(\mathcal{M}) \approx 0.03 \left(\frac{\mathcal{M}}{\mathcal{M}_{\odot}} \right)^{-1.35} \quad (5)$$

It is not yet clear whether the steeper drop of ξ for masses larger than $10 \mathcal{M}_{\odot}$ is a real effect, since in this region masses and bolometric corrections are not known very accurately and the number of such stars reasonably near the galactic plane is small.

Invited Review

Galactic Stellar and Substellar Initial Mass Function¹

GILLES CHABRIER

Ecole Normale Supérieure de Lyon, Centre de Recherche Astrophysique de Lyon, UMR CNRS 5574, 69364 Lyon Cedex 07, France; chabrier@ens-lyon.fr

1.1. Historical Perspective

Since the pioneering paper of Salpeter (1955), several fundamental reviews on the Galactic stellar mass function (MF) have been written by, in particular, Schmidt (1959), Miller & Scalo (1979, hereafter MS79), and Scalo (1986). A shorter, more recent discussion is given by Kroupa (2002). The determination of the stellar MF is a cornerstone in astrophysics, for the stellar mass distribution determines the evolution, surface brightness, chemical enrichment, and baryonic content of galaxies. Determining whether this MF has been constant along the evolution of the universe or varies with redshift bears crucial consequences on the so-called cosmic star formation, i.e., on the universe's light and matter evolution. Furthermore, the knowledge of the MF in our Galaxy yields the complete census of its stellar and substellar population and provides an essential diagnostic to understand the formation of starlike objects. As emphasized by Scalo (1986), **the stellar and substellar mass distribution is the link between stellar and galactic evolution.**

...

(from the **Conclusions**)

This IMF determination is examined in the context of star formation theory. Theories based on a **pure Jeans-type mechanism**, where fragmentation is due only to gravity, appear to have **difficulties explaining the determined IMF** and various observational constraints on star formation. On the other hand, **recent numerical simulations of compressible turbulence, in particular in super-Alfvénic conditions, reproduce qualitatively and reasonably quantitatively the determined IMF** and thus provide an appealing solution. In this picture, **star formation is induced by the dissipation of large-scale turbulence to smaller scales through radiative shocks, producing filamentary structures. These shocks produce local, nonequilibrium structures with large density contrasts. Some of these dense cores then collapse eventually in gravitationally bound objects under the combined action of turbulence and gravity.** The concept of a single Jeans mass, however, is replaced by a **distribution of local Jeans masses, representative of the lognormal probability density function of the turbulent gas.** Cores exceeding the average Jeans mass ($1 M_{\odot}$) naturally collapse into stars under the action of gravity, whereas objects below this limit still have a possibility to collapse, but with a decreasing probability, as gravity selects only the densest cores in a certain mass range (the ones such that the mass exceeds the local Jeans mass m_J). This picture, combining turbulence as the initial mechanism for fragmentation and gravity, thus provides a natural explanation for a scale-free power-law IMF at large scales and a broad lognormal form below about $1 M_{\odot}$. **Additional mechanisms such as accretion, subfragmentation of the cores, and multiplicity will not significantly affect the high-mass power-law part of the mass spectrum but can modify the extension of its low-mass part.** The initial level of turbulence in the cloud and its initial density can also affect the low-mass part of the IMF.

seems to give a "Salpeter" IMF*

(as high-mass end of underlying log-normal distribution, caused by...central limit theorem)

IMF. A large set of medium-size simulations is used to test the sink particle scheme, while larger simulations are used to test the numerical convergence of the IMF and the dependence of the IMF turnover on physical parameters predicted by the turbulent-fragmentation model. We find clear evidence of numerical convergence and strong support for the model predictions, including the initial time evolution of the IMF. We conclude that the physics of isothermal MHD turbulence is sufficient to explain the origin of the IMF.

ABSTRACT

After studying how line width depends on spatial scale in low-mass star-forming regions, we propose that “dense cores” (Myers & Benson 1983) represent an inner scale of a self-similar process that characterizes larger scale molecular clouds.

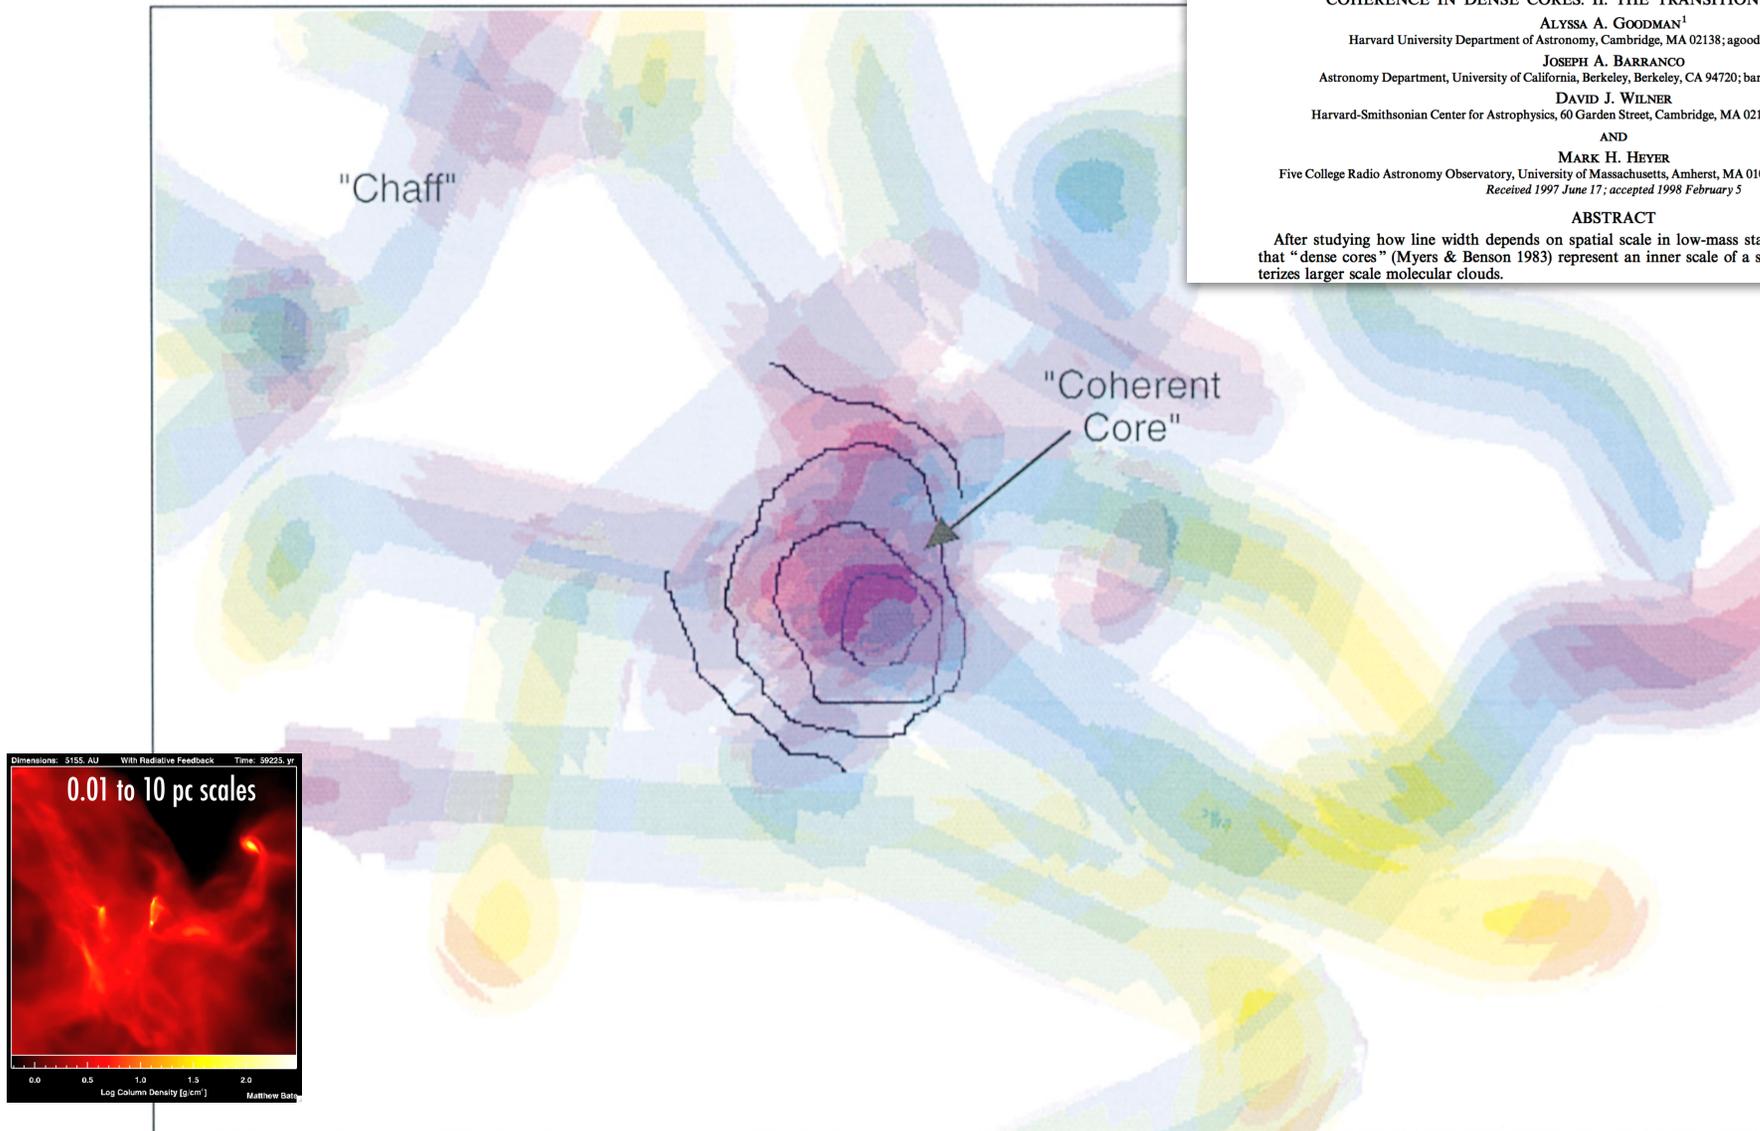

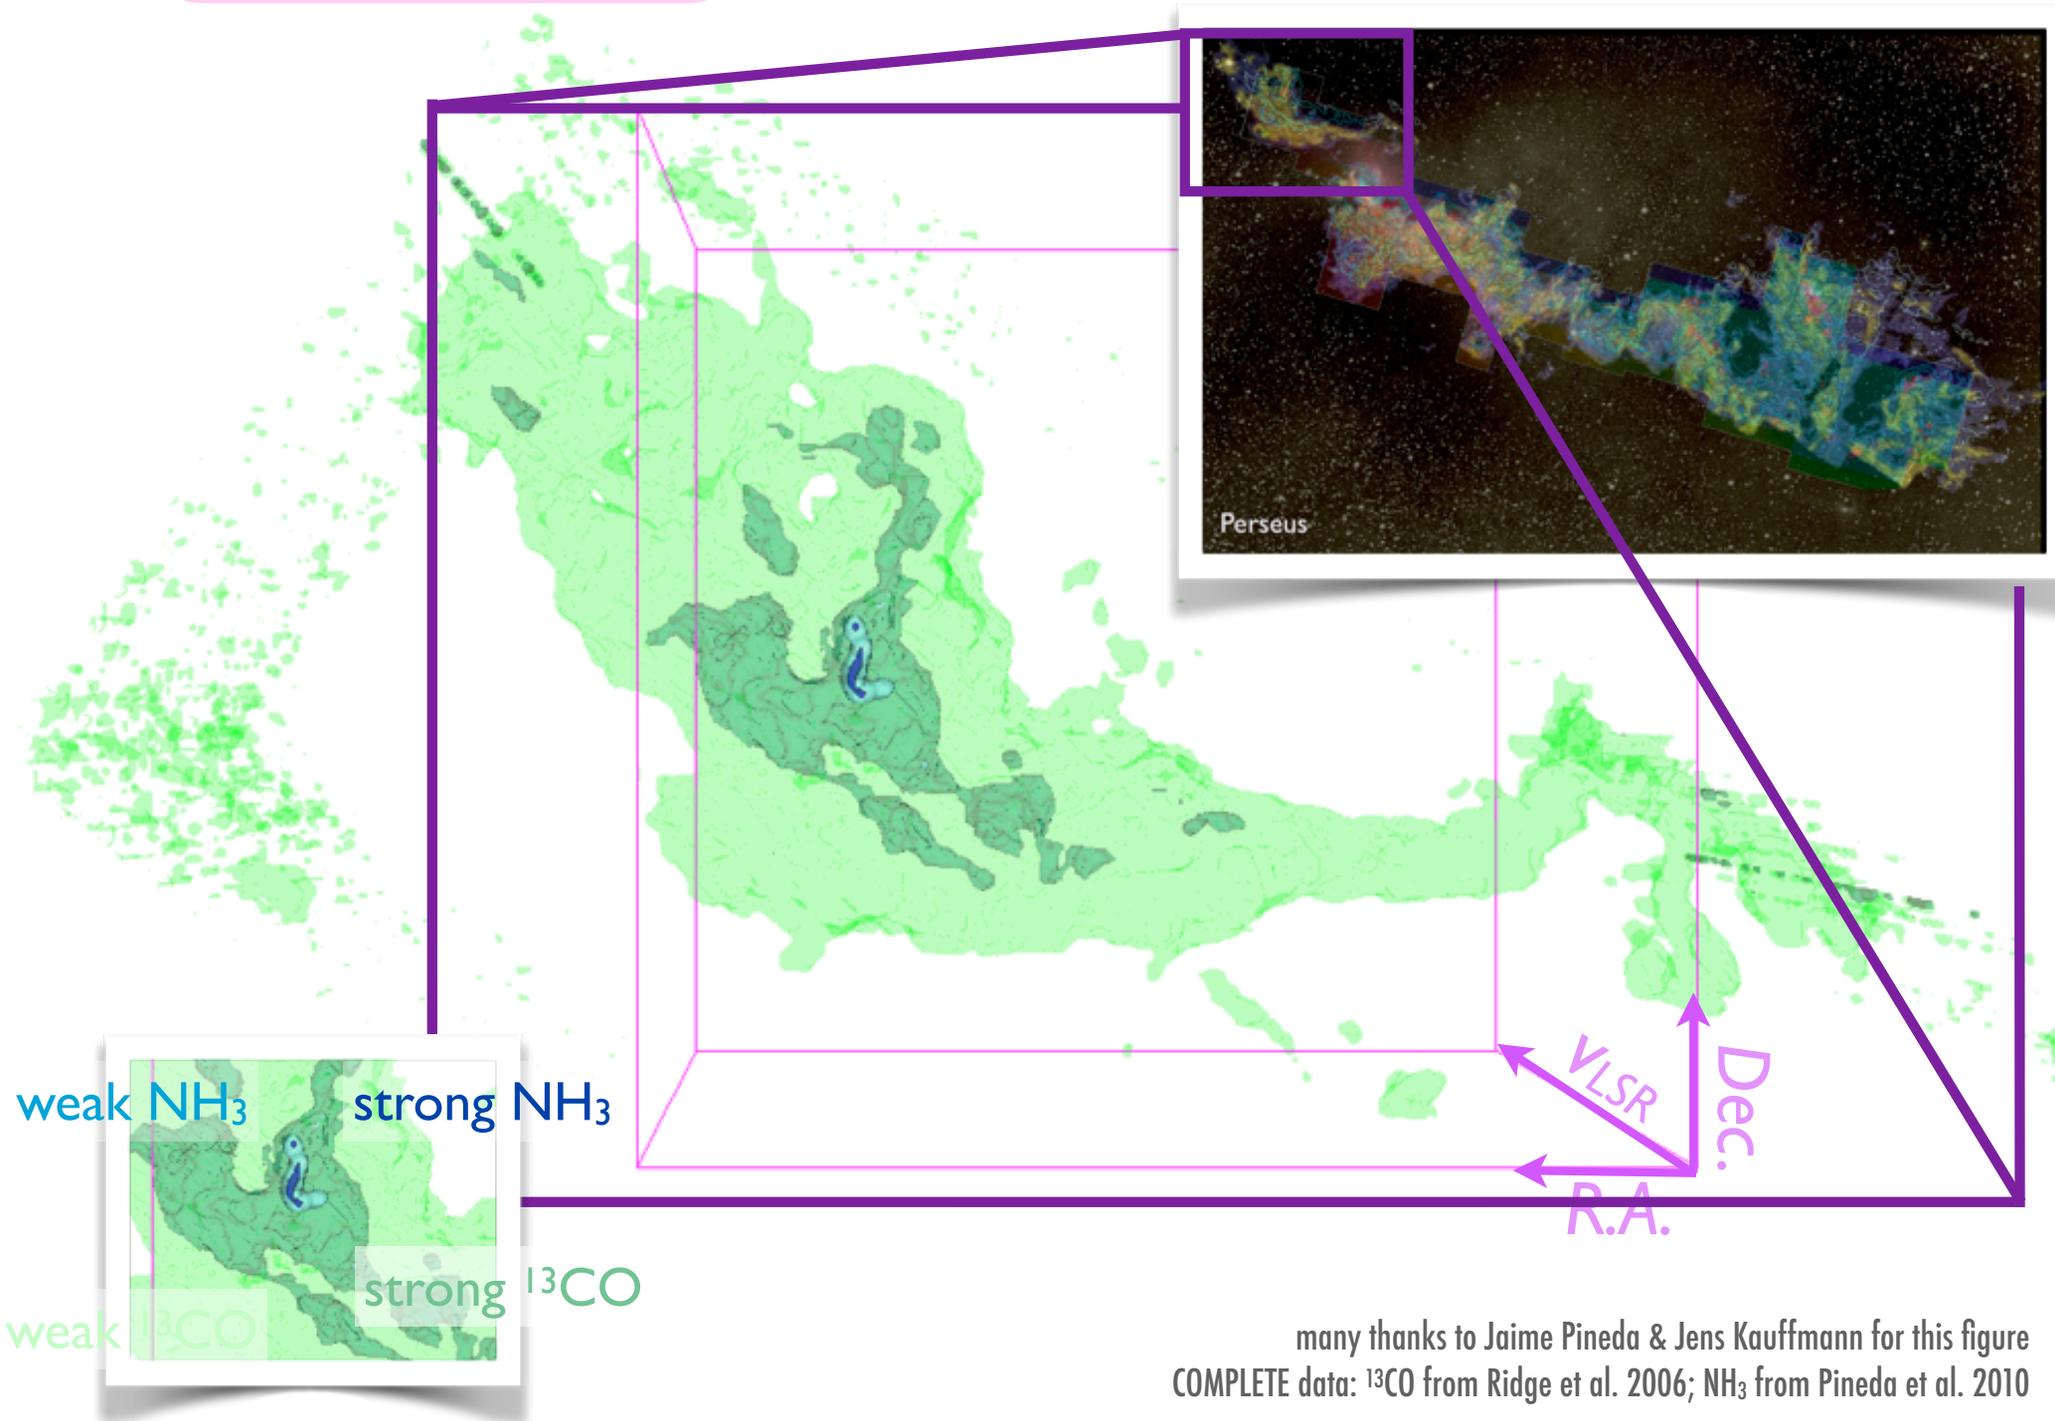

FIG. 10.—An illustration of the transition to coherence. Color and shading schematically represent velocity and density in this figure. On large scales, material (labeled chaff) is distributed in a self-similar fashion, and its filling factor is low. On scales smaller than some fiducial radius, the filling factor of gas increases substantially, and a coherent dense core, which is not self-similar, is formed. Due to limitations in the authors' drawing ability, the figure emphasizes a particular size scale in the chaff, which should actually exhibit self-similar structure on all scales ranging from the size of an entire molecular cloud complex down to a coherent core.

The formation of a quadruple star system with wide separation

Jaime E. Pineda¹, Stella S. R. Offner^{2,3}, Richard J. Parker⁴, Héctor G. Arce⁵, Alyssa A. Goodman⁶, Paola Caselli⁷, Gary A. Fuller⁸, Tyler L. Bourke^{9,10} & Stuart A. Corder^{11,12}

The initial multiplicity of stellar systems is highly uncertain. A number of mechanisms have been proposed to explain the origin of binary and multiple star systems, including core fragmentation, disk fragmentation and stellar capture^{1–3}. Observations show that protostellar and pre-main-sequence multiplicity is higher than the multiplicity found in field stars^{4–7}, which suggests that dynamical interactions occur early, splitting up multiple systems and modifying the initial stellar separations^{8,9}. Without direct, high-resolution observations of forming systems, however, it is difficult to determine the true initial multiplicity and the dominant binary formation mechanism. Here we report observations of a wide-separation (greater than 1,000 astronomical units) quadruple system composed of a young protostar and three gravitationally bound dense gas condensations. These condensations are the result of fragmentation of dense gas filaments, and each condensation is expected to form a star on a timescale of 40,000 years. We determine that the closest pair will form a bound binary, while the quadruple stellar system itself is bound but unstable on timescales of 500,000 years (comparable to the lifetime of the embedded protostellar phase¹⁰). These observations suggest that filament fragmentation on length scales of about 5,000 astronomical units offers a viable pathway to the formation of multiple systems.

Detailed knowledge of the underlying distribution of dense gas is the key to determining which structures will go on to form stars. Here we identify the dense gas structures that are most likely to form stars using the dendrogram technique²¹. Dendrogram analysis is a hierarchical structure decomposition that uses isocontours to identify individual features, while also determining where these contours merge with adjacent structures to create a new parental structure. We refer to the smallest scale (and brightest) structures in the dendrogram as condensations. These are the most likely places for an individual star to form. Figure 1a shows the B5 region as seen in dense gas (number density of H_2 , $n_{\text{H}_2} \approx 10^4 \text{ cm}^{-3}$), with the protostar and the identified gas condensations shown by a star and circles, respectively. The mass of the well-known protostar B5-IRS1 is 0.1 solar masses (M_{Jup} ; ref. 22), while the masses of condensations B5-Cond1, B5-Cond2 and B5-Cond3 are $0.36 \pm 0.09 M_{\text{Jup}}$, $0.26 \pm 0.12 M_{\text{Jup}}$ and $0.30 \pm 0.13 M_{\text{Jup}}$, respectively. Uncertainty in these masses is dominated by the uncertainty in the temperature used to convert measured fluxes to masses. The radii of the three condensations are respectively 2,800 AU, 2,300 AU and 2,500 AU, while the projected separations between the same three condensations and the protostar are 3,300 AU, 5,100 AU and 11,400 AU (see Methods). The half-mass radii of the condensations are about half the condensation radii. This, combined with

ON THE PHYSICS OF DUST GRAINS IN HOT GAS

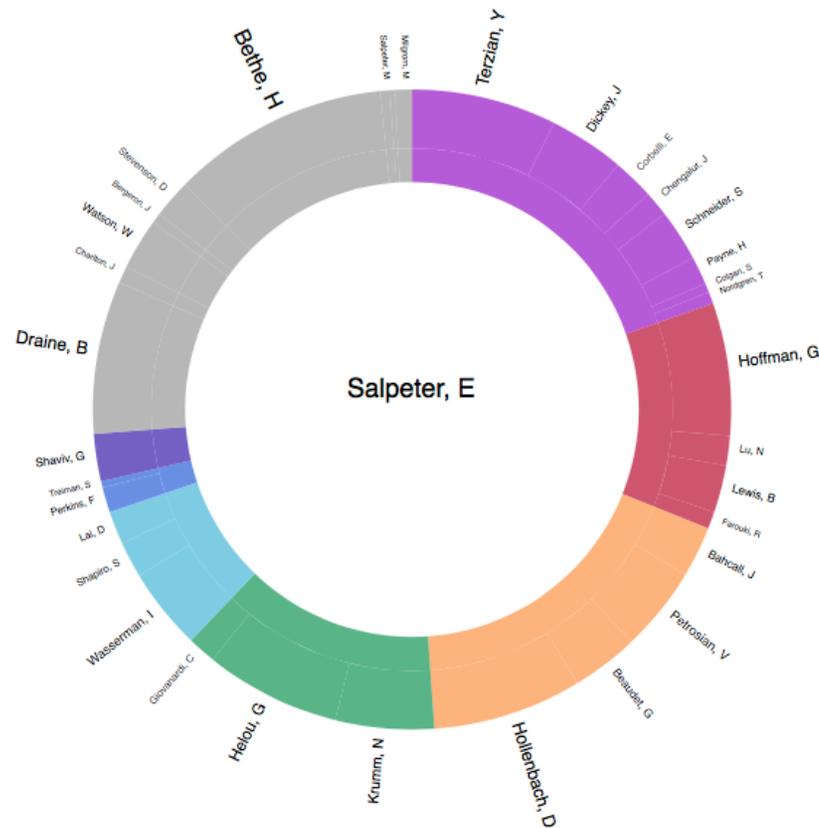

B. T. DRAINE
 Harvard-Smithsonian Center for Astrophysics

AND
 E. E. SALPETER
 Departments of Astronomy and Physics, Cornell University
 Received 1978 August 7; accepted 1979 January 8

ABSTRACT

Charging of dust grains in hot (10^4 – 10^9 K) plasma is studied, including photoelectron and secondary electron emission, field emission, and transmission of electrons and ions through the grain; resulting grain potentials are (for $T \gtrsim 10^5$ K) considerably smaller in magnitude than found by Burke and Silk. Even so, large electrostatic stresses can cause ion field emission and rapid destruction of small grains in very hot gas. Rapid rotation can also disrupt small grains, but damping (by microwave emission) usually limits the centrifugal stress to acceptable values for plasma densities $n_H \lesssim 1 \text{ cm}^{-3}$. Sputtering rates are estimated for grains in hot gas, based upon a semiempirical fit to experimental data. Predicted sputtering rates for possible grain constituents are similar to estimates by Barlow, but in some cases differ significantly. Useful approximation formulae are given for the drag forces acting on a grain with arbitrary Mach number.

SURFACE RECOMBINATION OF HYDROGEN MOLECULES

DAVID HOLLENBACH
 Harvard College Observatory, Cambridge, Massachusetts

AND
 E. E. SALPETER
 Laboratory of Nuclear Studies, Cornell University, Ithaca, New York
 Received 1970 March 24; revised 1970 June 3

ABSTRACT

In this paper we reexamine the problem of the formation of molecular hydrogen on the surfaces of dust grains. We discuss a "recombination efficiency" $\gamma'(T)$, the fraction of adsorbed atoms which form molecules before evaporating from a surface, as a function of the surface temperature T . For grains with a perfectly regular surface, γ' would be small at grain temperatures exceeding about 13° K. We consider an irregular surface with some lattice-defect or impurity sites having enhanced adsorption energies for atomic hydrogen. Our main result is that even a small number of such sites can greatly extend the range of temperatures over which the efficiency of molecular formation is high. On realistic grains, $\gamma' \simeq 1$ for all $T < T_u$, where T_u is some critical value between 25° and 50° K. Since all dust grains in H I regions are likely to be cooler than T_u , we conclude that $\gamma' = 1$ for molecular formation on grains in H I regions.

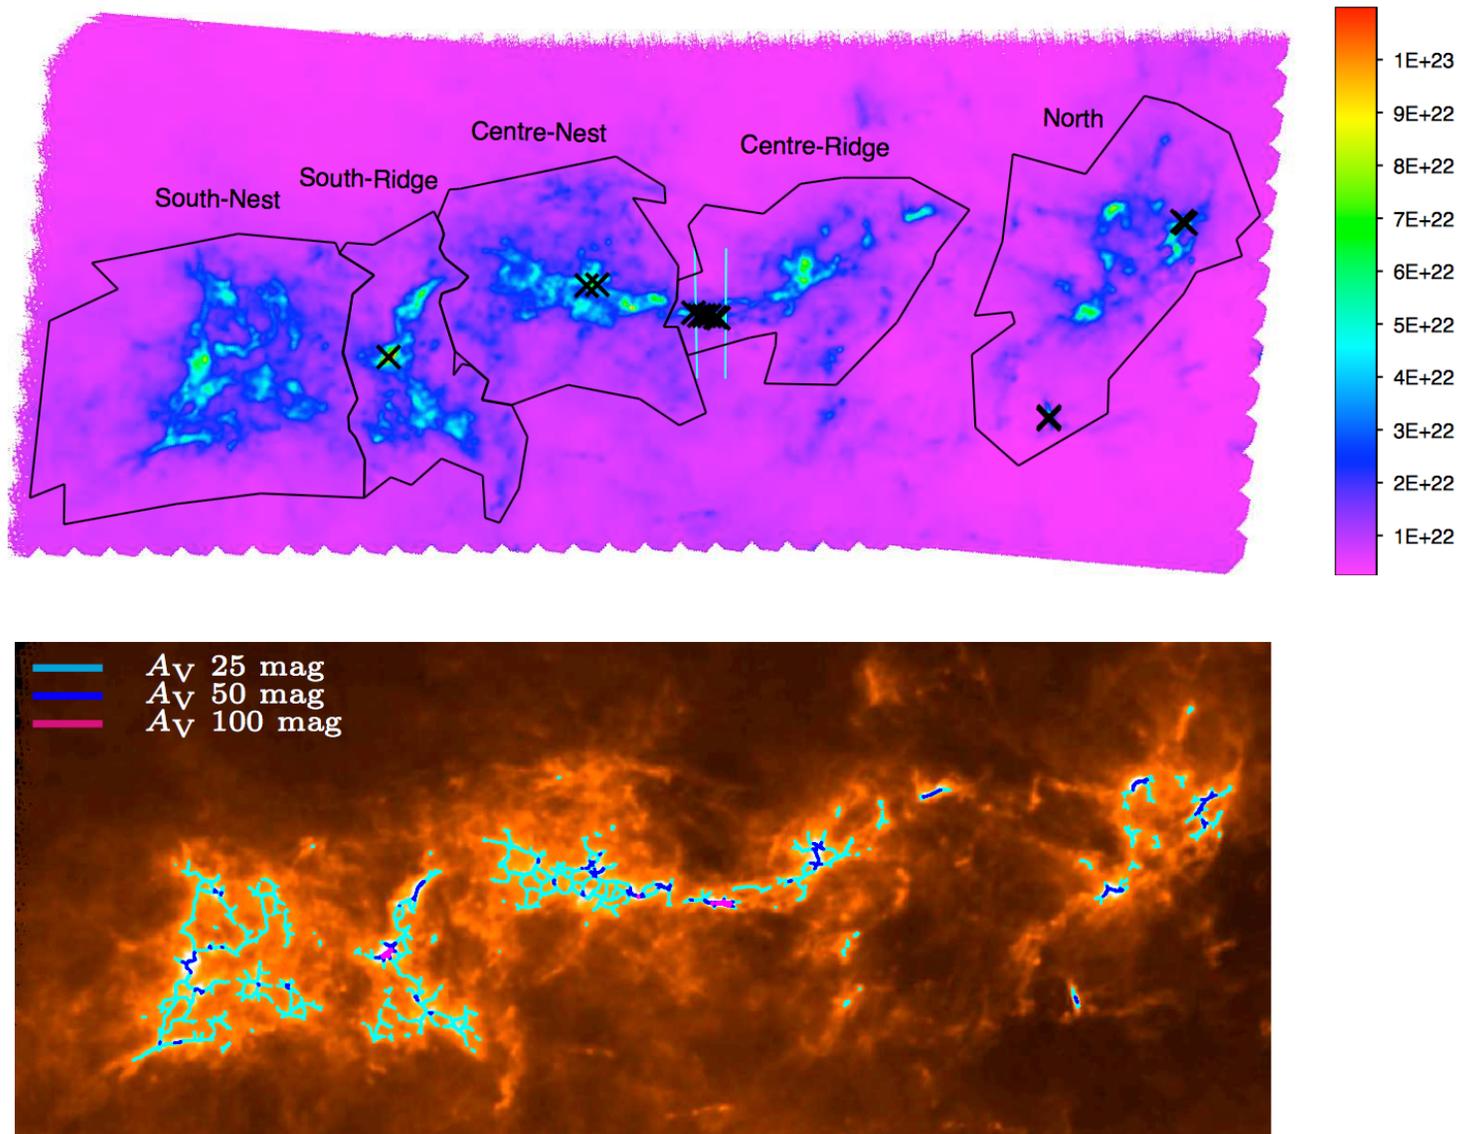

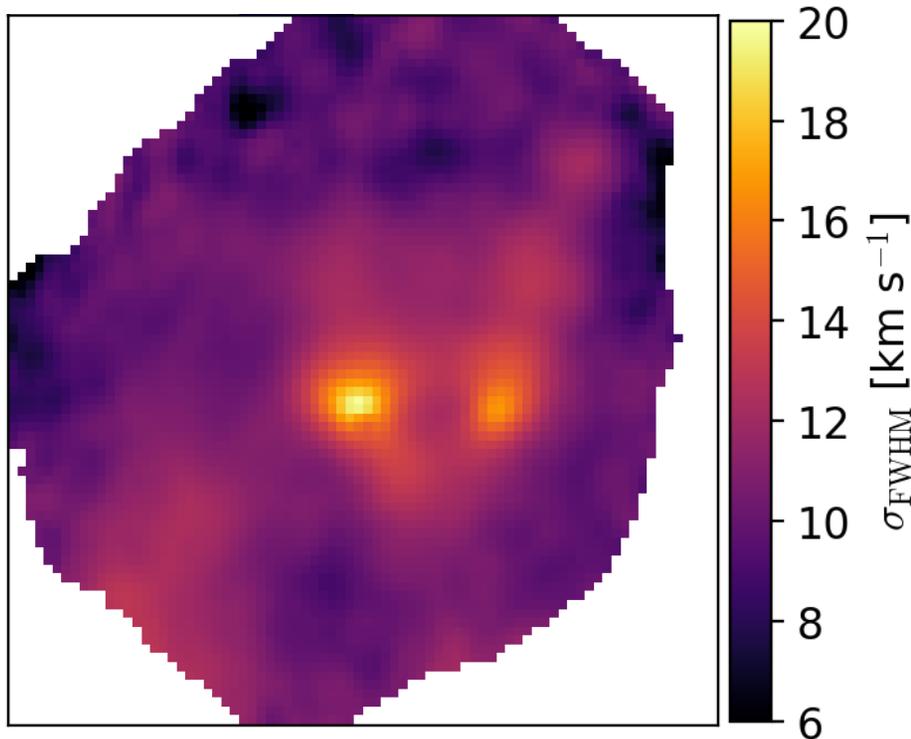

Figure 1: Top: Column Density map with sub-regions, as defined at an $A_V > 7$ mag, overlaid. The black crosses are the 13 most massive sources with ($S:N > 50$, and Mass $20\text{--}60M_\odot$). Bottom: Column density with the filamentary structure detected by DisPerSE. Ridges appear magenta.
