ABSTRACT: Ammonia (NH₃) is a key precursor species to atmospheric fine particulate matter with strong implications for regional air quality and global climate change. NH₃ from vehicles accounts for a significant fraction of total emissions of NH₃ in urban areas. A mobile platform is developed to measure NH₃, CO, and CO₂ from the top of a passenger car. The mobile platform conducted 87 h of on-road measurements, covering 4500 km in New Jersey and California. The average on-road emission factor (EF) in CA is 0.49 ± 0.06 g NH₃ per kg fuel and agrees with previous studies in CA (0.3–0.8 g/kg). The mean on-road NH₃:CO emission ratio is 0.029 ± 0.005, and there is no systematic difference between NJ and CA. On-road NH₃ EFs increase with road gradient by an enhancement of 53 mg/kg fuel per percentage of gradient. On-road NH₃ EFs show higher values in both stop-and-go driving conditions and freeway speeds with a minimum near 70 km/h. Consistent with prior studies, the on-road emission ratios suggest a highly skewed distribution of NH₃ emitters. Comparisons with existing NJ and CA on-road emission inventories indicate that there may be an underestimation of on-road NH₃ emissions in both NJ and CA. We demonstrate that mobile, open-path measurements provide a unique tool to help quantitatively understand the on-road NH₃ emissions in urban and suburban settings.

INTRODUCTION

Ammonia (NH₃) is a key component of the global nitrogen cycle. As the dominant alkaline atmospheric species, NH₃ reacts readily with atmospheric acidic species to form fine particulate matter (PM₂.₅), which has implications for regional air quality and global climate change.1,2 However, the global sources of NH₃ are subject to considerable uncertainties.3 The magnitude and trends of emissions from different source types and source regions are even more uncertain. Comparisons between atmospheric modeling and satellite observations imply that current NH₃ inventories are underestimated globally.4,5 Agricultural cropland/soil and livestock farming are the major sources of atmospheric NH₃ and account for over 60% of the global inventory.6,7 NH₃ is also a byproduct of fossil fuel combustion, especially from vehicles equipped with three-way catalytic converters (TWC).8 Existing atmospheric measurements suggest that traffic may provide significant amounts of NH₃ in urban areas,8–11 although, on a global scale, on-road traffic emissions of NH₃ are considerably smaller compared to agricultural activities. On-road NH₃ emissions may cause greater impact on air quality and human health, because significant sources of other PM₂.₅ precursors (SO₂, NOₓ) are usually collocated in heavily populated urban areas.12 The US EPA monitors ambient NH₃ concentrations in the Passive Ammonia Monitoring Network (AMoN), but NH₃ has not been regulated or controlled from vehicle emissions.13

Vehicular NH₃ emissions have been characterized by chassis dynamometer testing,9,13–18 roadside remote sensing,19–22 and tunnel measurements.23,24 Carbon monoxide (CO) and carbon dioxide (CO₂) were usually measured simultaneously to calculate NH₃ emission factors (EFs) and quantify NH₃ emissions. NH₃ EFs are defined as grams of NH₃ emitted per kilogram of fuel burned. NH₃ is especially difficult to measure due to its strong affinity to the instrument surfaces. Its rapid partitioning between gas and particle phase also complicates instrument design.25 Despite that NH₃ was recognized in vehicle emissions in the 1980s,26 it is still challenging to represent its real-world emission patterns. Chassis dynamometers can test only a limited range of driving conditions and number of vehicles, whereas on-road NH₃ EF measurements showed substantially skewed distributions, large variances, and time dependence.20,22 Hence chassis dynamometer tests are not likely representative of the emission patterns of entire vehicle fleets.27 Roadside remote sensing and tunnel measurements are stationary, which capture representative fleet averages, but they can only characterize emission patterns at a limited number of sites. Furthermore, these sites are often located in tunnels with...
significant road gradients (e.g., Caldecott tunnel with a 4% upgrade\textsuperscript{24,28} or on freeway ramps where vehicles drive at low speed, high acceleration, and usually in the presence of a road gradient.\textsuperscript{59} The EFs of NH\textsubscript{3}, CO, and NO\textsubscript{x} have all been shown to have significant positive correlations with vehicle specific power and/or positive road gradients.\textsuperscript{17,29–31} There are additional challenges to identify roadside measurement sites representative of the route average emissions.\textsuperscript{15} Otherwise, EFs are likely biased as uphill driving and high acceleration contribute to high EFs.\textsuperscript{17,28,30}

Mobile platforms equipped with fast-response sensors have been previously deployed to quantify on-road emissions.\textsuperscript{28,32,33} Mobile on-road measurements can capture emissions under a full range of real-world driving conditions and road conditions. They can also achieve large spatial coverage and measure the average emissions of the entire fleet. Nevertheless, there have been few on-road mobile NH\textsubscript{3} measurements and knowledge about real-world NH\textsubscript{3} EFs is limited. Compared to existing state-of-the-art NH\textsubscript{3} sensors, mobile, open-path sensors are advantageous to quantify on-road emissions. Open-path design shows higher time resolution and faster response.\textsuperscript{34–37} It avoids significant adsorption/desorption effects between NH\textsubscript{3} and the instrument surfaces. The delay of response caused by these surface effects may bias the results when NH\textsubscript{3} emission ratios are calculated with other nonsticky tracers, like CO and CO\textsubscript{2}. Meanwhile, there is no need to use a powerful pump, which makes the open-path sensors much more portable and adaptable for frequent, long-time on-road measurements.

In this study, we perform measurements with a mobile platform consisting of an open-path NH\textsubscript{3} sensor, an open-path CO sensor, and an open-path CO\textsubscript{2} sensor, all of which are mounted on the top of a passenger car. CO is widely used as a tracer for combustion processes, and the sum of CO and CO\textsubscript{2} provides quantification of vehicle fuel consumption. The high time resolution (\(\geq 1\) Hz) and fast response of the open-path sensors are especially advantageous for capturing transient concentration changes. The collocation of open-path sensors makes it straightforward to calculate real-time emission ratios. We present both roadside measurements and a series of on-road measurements in a wide range of driving conditions. Our scientific goal is to quantify on-road NH\textsubscript{3} emissions in urban and suburban settings to understand how driving conditions influence on-road NH\textsubscript{3} emissions by making both roadside measurements and a series of on-road measurements under a wide range of driving conditions.

\section*{EXPERIMENTAL METHODS}

The mobile platform was designed as a 91 \(\times\) 30 cm breadboard mounted on the base of a car rack, which readily fits on top of most passenger cars. The open-path NH\textsubscript{3} and CO sensors have been described in detail previously in Miller et al.\textsuperscript{38} and Tao et al.\textsuperscript{37} Only a brief summary is presented here.

Two continuous wave (CW) thermoelectric-cooled distributed feedback (DFB) quantum cascade lasers (QCLs) are used to detect NH\textsubscript{3} and CO at 9.062 and 4.538 \(\mu\)m, respectively. The NH\textsubscript{3} absorption feature at 9.062 \(\mu\)m was selected to optimize the sensitivity while minimizing the interferences from the other species in open-path detection. These two lasers are coupled into multipass optical cells with path lengths of 36 and 16 m, respectively. Wavelength modulation spectroscopy (WMS) is used to enhance the signal-to-noise ratio. The second harmonic (2\(\pi\)) detection in WMS also helps resolve air-broadened absorption lines.\textsuperscript{38–40} Detector waveforms are acquired at 50 Hz and coaveraged at 10 Hz. A built-in virtual lock-in amplifier retrieves NH\textsubscript{3} and CO concentrations from the averaged waveforms. Calibration is performed by normalizing an inline ethylene (C\textsubscript{2}H\textsubscript{4}) reference cell signal in the NH\textsubscript{3} system and an inline acetylene (C\textsubscript{2}H\textsubscript{2}) reference cell signal in the CO system. The purpose of the inline reference cells is to provide a constant signal that is continuously probed and can be used to account for sensor drift.\textsuperscript{50} The accuracies are 10% for NH\textsubscript{3} and 5% for CO, calibrated in situ by the inline reference cells as well as direct absorption spectroscopy. The NH\textsubscript{3} sensor was not calibrated by direction absorption spectroscopy in NJ, which limits the accuracy to 20%.\textsuperscript{56} The NH\textsubscript{3} precision is 0.15 ppbv\textsuperscript{38} and the CO precision is 0.36 ppbv\textsuperscript{35} at 10 Hz.

A commercial CO\textsubscript{2} sensor, LICOR LI-7500 open-path CO\textsubscript{2}/H\textsubscript{2}O analyzer, was placed on the mobile platform. The CO\textsubscript{2} sampling frequency was set to 5 Hz with an accuracy <1% and a precision of 0.08 ppmv CO\textsubscript{2}. The CO\textsubscript{2}/H\textsubscript{2}O analyzer was mounted next to the multipass cells of the NH\textsubscript{3} and CO sensors, so the sampling volumes of the sensors have a footprint of 50 \(\times\) 50 cm. Meteorological parameters were measured by a portable weather station (Vaisala WXT520). Geolocation, car speed, and driving direction were recorded by a GPS unit (GlobalSat EM-406a). All the measurements were averaged at 1 Hz and synchronized with the GPS time stamp. The covariance plots show that NH\textsubscript{3} and CO\textsubscript{2} measurements are synchronized to within 1 s and have similar time response (Supporting Information, Figure S1). Road conditions were recorded by two GoPro Hero3 cameras mounted on the front and back side of the platform. A picture of the mobile platform is shown in the TOC art. All sensors operate on two 12 V car batteries. Emissions from our own vehicle were periodically checked by driving to a relatively clean area with no other traffic emissions. A detailed description of our identification of self-emissions from the measurement vehicles is provided in the Supporting Information (Figure S2).

To derive the emission ratios and EFs from vehicles, we separate the measurements into a slowly varying background and rapidly changing peaks due to individual vehicles. Following the method described by Hudda et al.,\textsuperscript{28} we use the lowest percentiles of pollutant concentrations observed during a certain time window as baseline values. A trend line is linearly interpolated between these baseline values. Subtracting the trend lines from the concentration measurements yields the emission enhancement data: \(\Delta[\text{NH}_3]\), \(\Delta[\text{CO}]\), and \(\Delta[\text{CO}_2]\). Sensitivity studies were conducted by calculating emission ratios using a range of time window size (1–30 min). The results show that emission ratio calculation converges within \(\pm 5\%\) for time window size of 5–15 min, which indicates that these window sizes are sufficient to separate short time scale vehicle emissions from the long-term regional background. We use a time window of 12 min for consistency. Given that the atmospheric lifetime of NH\textsubscript{3} is about 11 h,\textsuperscript{41} and that we are close to the emission sources, we neglect the deposition and phase changes of NH\textsubscript{3} and define NH\textsubscript{3}:CO and NH\textsubscript{3}:CO\textsubscript{2} emission ratios as \(\Delta[\text{NH}_3]/\Delta[\text{CO}]\) and \(\Delta[\text{NH}_3]/\Delta[\text{CO}_2]\). Empirical cutoffs were selected to exclude data close to the background levels, and thereby to avoid negative and spuriously large values.\textsuperscript{42} The ratio calculation is limited to \(\Delta \text{CO}\) greater than 100 ppbv and \(\Delta \text{CO}_2\) greater than 15 ppmv. The emission ratio distributions are insensitive to the cutoffs, and the mean changes within 5% when doubling the cutoffs.
RESULTS AND DISCUSSION

Controlled Roadside Measurements. To demonstrate that our sensors could capture the rapid change of concentration and emission ratio with high resolution and sensitivity from individual cars, we deployed the mobile platform in a controlled environment on January 5, 2012. Only NH\textsubscript{3} and CO were measured. The sensors were located inside a parking garage and about 5 m from the exit. The driving speed near the sensor was 7–15 km/h and the vehicles were generally 2–5 m away from the sensor when passing by. The vehicles in the garage were mostly driven by commuters. There were no other significant local sources of NH\textsubscript{3} and CO besides vehicle emissions on campus. We first conducted a static measurement with a 2002 Honda Accord, which uses a three-way catalytic converter. For this test, there were no other vehicles entering or exiting the garage, and the CO concentration was close to the regional background value of 300 ppbv. Figure 1a shows measurements of NH\textsubscript{3} and CO from the car parked 3 m away from the sensor. The variations of NH\textsubscript{3} and CO trace well with each other, and no delay was observed at high time resolution (10 Hz). Initially, the engine was running at an idle speed of 1000 rpm. The measured concentrations varied due to eddy diffusion but the NH\textsubscript{3}:CO emission ratio was almost constant ($\Delta$[NH\textsubscript{3}]/$\Delta$[CO] = 0.03 ppbv/ppbv). Fuel-rich driving conditions were simulated by increasing the engine speed to 2500 rpm, a typical RPM during modest acceleration. As shown by Figure 1b, the NH\textsubscript{3}:CO ratio increased significantly when the engine ran fuel-rich, with $\Delta$[NH\textsubscript{3}]/$\Delta$[CO] = 0.1 ppbv/ppbv. Although this individual car measurement does not represent the engine load in the real world, the result is qualitatively consistent with the literature. A number of previous studies showed that NH\textsubscript{3} formation can be attributed primarily to the reaction of nitric oxide (NO) with hydrogen gas produced from the water–gas shift reaction between CO and water. The hydrogen gas reduces NO to form NH\textsubscript{3} through multiple known and proposed pathways. Fuel-rich driving conditions are generally associated with more NO and CO supply and high temperature, which favor NH\textsubscript{3} formation. Most literature report high NH\textsubscript{3} emission ratios during fuel-rich driving conditions.

To verify the representativeness of the individual car, we then measured 320 cars leaving the garage (flat surface, coasting to a stop sign). The measurement time, spatial coverage, and ambient temperature of this and the following measurements are listed in Table S1 (Supporting Information). The models of each vehicle driven by the sensor were recorded together with the point in time when each individual vehicle passed. The majority were midclass passenger cars with model years from 2000 to 2007. Honda (17%) and Toyota (16%) were the manufacturers with the largest number of vehicles. Because the measurements were performed during the evening rush hour of a winter day, most vehicles were near cold start conditions when passing the sensors. The average NH\textsubscript{3}:CO emission ratio from the 320 cars in the garage is 0.019 ± 0.005 ppbv/ppbv, where the uncertainty is estimated from the measurement uncertainties of NH\textsubscript{3} and CO. This distribution is highly skewed, indicating a small number of high emitters and a majority of low emitters.

On-Road NH\textsubscript{3} Concentration Measurements. Three days of on-road NH\textsubscript{3} measurements were performed near Princeton, NJ on September 20 (drive #1), October 17 (drive #2), and November 11 (drive #3), 2012. CO was only measured in drive #3 due to sensor availability. The mean on-road NH\textsubscript{3}:CO emission ratio was 0.029 ± 0.007 ppbv/ppbv in drive #3. The largest spatial and temporal coverage was performed in drive #2, covering a range of routes, including a six-lane urban highway with large traffic volumes (US Route 1, traffic volume ∼10\textsuperscript{5} vehicles/day), an urban–suburban road (County Route 533, traffic volume ∼3 × 10\textsuperscript{4} vehicles/day), and a suburban–rural road (County Route 614, traffic volume ∼10\textsuperscript{4} vehicles/day).

The same routes on US Route 1 near Princeton were covered 3 times between 15:22 and 17:29 in drive #2, during which the traffic density continuously built up. Figure 2 illustrates the time evolution of NH\textsubscript{3} concentration distribution on US 1 toward the evening rush hour. The traffic density built up substantially during the second and third drive, and there were much more stop-and-go driving conditions. Our mean speed was only 43 km/h and 32 km/h in the last two drives, whereas the speed limit is 88.5 km/h. As the travel density built up, there were more acceleration events, which favor NH\textsubscript{3} generation in the TWC and contribute to the heavy tails toward higher NH\textsubscript{3} concentrations.

Figure 3 shows the correlations between NH\textsubscript{3} concentrations and traffic densities. The New Jersey Department of Transportation made hourly traffic counts during three consecutive days in 2009–2011 at nine locations along our driving route. We segmented our driving routes in drive #2 according to their...
proximity to these traffic count locations. In many cases, we drove by traffic count locations multiple times. Detailed information on the driving time near each traffic count locations is listed in Table S2 in the Supporting Information. Significant positive correlations are found between the mean NH₃ concentrations on the segmented routes and traffic densities (correlations are significant at a level of 0.001). The 95 percentiles show a much larger slope (18 ppbv per 1000 vehicles/h), indicating that a relatively small percentage of the vehicle fleet emits a significant proportion of NH₃.

**NH₃ Emission Factors and Driving Conditions.** The mobile platform was fully equipped in California from January 21 to February 7, 2013, as part of the NASA DISCOVER-AQ campaign. We covered 4300 km, including two major urban–suburban areas (San Francisco Bay area and Los Angeles Basin) and the suburban–rural areas in the San Joaquin valley. The total driving time was 81 h. In this section, we investigate the dependence of NH₃ emissions on road gradient on the freeways in the SF Bay area, where traffic speed was almost constant. We also investigate NH₃ emissions under a wide range of traffic speed in the Los Angeles Basin with no significant road gradient. The driving time and ambient conditions are summarized in Table S1 (Supporting Information).

On-road measurements were performed on I-580 on February 3 and US Route 101 on February 4 and 5 in the SF Bay area. In all three cases, the mean wind velocity was light and varied by less than 1 m/s, such that we did not account for wind direction in our analyses. Both I-580 and US Route 101 have significant road gradients, often up to ±7% gradient (Figure S3–4, Supporting Information). Emission ratios are calculated using data measured on I-580 west bound in the East Bay area and on US 101 south bound in the North Bay area. Both routes are eight-lane freeways mainly in suburban areas (Supporting Information, Figure S5) and in free-flowing driving conditions. We drove at a constant speed in lane #3 (the central right lane) whenever it was possible. The driving speed was 92 ± 5 km/h, slightly lower than the speed limit, which ensured sampling the exhaust plumes produced by a variety of passing vehicles. The road gradient was derived by the instantaneous pressure gradient and GPS speed using the hydrostatic equation, with an uncertainty of 0.5% (eq 1 and associated text in the Supporting Information).

Emission ratios are calculated using NH₃, CO, and CO₂ concentrations, following the method introduced in the previous section. Figure 4 shows the dependence of NH₃:CO₂ and CO:CO₂ emission ratios on the road gradient. The emission ratio data are binned into 11 road gradient intervals, so that each bin has at least 60 s of net emission data. The 5, 25, 50, 75, and 95 percentiles of emission ratios within

---

**Figure 2.** Time evolution of on-road NH₃ concentration distribution on US 1.

**Figure 3.** Correlations between mean and 95 percentile NH₃ concentrations measured on the segmented routes and traffic densities. The intercepts were forced to the regional background of 16 ppbv.

**Figure 4.** NH₃:CO₂ and CO:CO₂ emission ratios with road gradient. Five and 95 percentiles are denoted by whiskers of boxes, 25 and 75 percentiles are denoted by lower and upper boundaries of boxes, medians are denoted by central lines, and means are denoted by blue dots.
each bin are displayed as box-and-whisker plots, together with the arithmetic mean. Large variations of emission ratios were observed. Even for the same vehicle, emission factors can vary by 2 orders of magnitude due to driving conditions, as shown by dynamometer studies. The variations among vehicles are also large, with skewed distributions, where the high emitters contribute to substantial fraction of total emissions. In spite of the variability, both the mean NH₃:CO₂ (Figure 4a) and mean CO₂:CO (Figure 4b) emission ratios showed significant enhancement when driving uphill. The variation of emission ratios was also higher. Tunnel studies have shown that driving uphill approximately doubled emission factors for CO compared to downhill, which generally agrees with our results. As CO plays a key role in the water–gas shift reaction, one should expect high NH₃ emissions as well.

The overall average NH₃:CO emission ratio is 0.031 ± 0.005 ppbv/ppbv, and it decreased with road gradient with an R² of 0.88 (Supporting Information, Figure S6). Although we have observed that for an individual car the NH₃:CO emission ratio increased with engine load in the garage measurements, the integrated on-road data show that CO emissions increased faster with road gradients and thus engine load than NH₃, which also agrees with roadside measurements.

Although CO is a more sensitive tracer for vehicle emissions than CO₂, CO₂ is more important to quantify NH₃ emission factors, as CO₂ constitutes the majority of vehicular carbon emissions by mole fraction. The NH₃ EFs are expressed per kilogram of fuel burned using a carbon balance approach:

\[
EF = \frac{\Delta [\text{NH}_3]}{\Delta [\text{CO}] + \Delta [\text{CO}]} \left( \frac{\text{MW}_{\text{NH}_3}}{\text{MW}_C} \right) \rho_C
\]

Here MW_{NH₃} and MW_C are the molecular weight of NH₃ and carbon. ρ_C = 0.85 is the mass fraction of carbon in gasoline. We neglect ρ_C of diesel (0.87) because diesel vehicles have been reported to have very limited contributions to on-road NH₃ emissions.

Figure 5 shows the correlation between the average NH₃ EFs and the positive road gradients. Linear regression indicates that NH₃ EFs increase by 53 mg/kg when the road gradient increases by 1%, with an R² of 0.92. Emission factors measured by existing roadside and tunnel measurements in California are also plotted with the reported road gradient. The EFs measured in this study generally span the range reported by various studies, even though the literature measurements were conducted in diverse conditions. The high value in West LA (2008) is likely due to the strong acceleration at the measurement site, with an average of 0.85 m/s². Higher NO₂ emission ratios were also reported in West LA site than other on-road emission ratio studies. On-road fleet variation may also contribute to the diversity of NH₃ EFs. Multiple roadside measurements have indicated that NH₃ EFs first increase and then decrease as a function of vehicle age, depending on two counteracting factors, catalyst reducing efficiency and NO (precursor of NH₃) emissions.

On January 27, 2013, we sampled NH₃ emission ratios in Los Angeles area. The driving route was mostly on flat terrain in the LA basin (Supporting Information, Figure S7). The total driving distance in the LA basin was 362 km, and driving time was 4.6 h. A wide range of driving speeds was sampled (Supporting Information, Figure S8). Zavala et al. classified their on-road measurements in Mexico City into stop-and-go, traffic, and cruise driving conditions, based on the speed of their mobile laboratory. Their results indicated that CO EFs decreased from stop-and-go to cruise driving conditions, whereas NO EFs showed a weak increasing trend. In this study, we binned the NH₃ EF data according to the speed of mobile platform to get a more continuous relationship between EFs and traffic speed. The results are shown in Figure 6. The first two bins generally represent stop-and-go driving conditions, bins 2–5 represent in-traffic driving on the city roads, and bins 6–7 are freeway-driving. NH₃ EFs first decrease and then increase at highway speed. This dependence can be attributed to the emissions of two key precursors, CO and NO. According to existing vehicle emission inventory, EFs of CO and NO have shown a decreasing trend with speed but switch to an increasing trend at highway speed.

In addition to the SF bay area and LA basin data, our measurements in three major cities (Fresno, Bakersfield, and Porterville) in the San Joaquin Valley were also added to include a wider range of driving conditions. Figure 7 shows the distribution of on-road NH₃ EFs measured in all the major urban areas covered during the DISCOVER-AQ campaign in California. Also shown in Figure 7 is the fit of a log-normal distribution. The EFs span about 4 orders of magnitude in range. The distribution of NH₃ EFs is almost symmetric at log scale (skewness = 0.045) but more peaked than a log-normal distribution.

Figure 5. NH₃ EFs increase with road gradients. Error bars are estimated based on the measurement uncertainties. Color-coded rectangles denote existing EF measurements with reported road gradient. The vertical extension of each rectangle denotes the reported uncertainties. LA (1999) refers to Baum et al. (2001). No quantitative road gradient was reported, but it should be within 1% according to Google Earth elevation data. Caldecott Tunnel (1999) refers to Kean et al., Caldecott Tunnel (2006) refers to Kean et al., San Jose, Fresno, and West LA (2008) refers to Bishop et al., and Van Nuys (2010) refers to Bishop et al.

Figure 6. NH₃ EFs with driving speed in LA. The boxes and whiskers are defined as in Figure 4.
distribution with a kurtosis of 3.5. The overall average of the EF data set is 0.49 g/kg, which generally falls within the range of the existing roadside measurements in California, as summarized in Figure 5.

CO was measured simultaneously in both New Jersey and California, and NH₃:CO emission ratios were used to assess on-road NH₃ sources. Nowak et al. used airborne gas/particulate NH₃ and CO measurements to quantify NH₃ emissions from automobile sources in the South Coast Air Basin (SoCAB) during the CalNex 2010 experiment. The mean NH₃:CO emission ratio reported downwind of the LA urban core was 0.033 ppbv/ppbv. The distributions of our NH₃:CO emission ratio measurements are shown as boxplots in Figure 8 together with the aircraft measurements over SoCAB. Because we measured in situ at the source location, we neglect the contributions of particulate phase ammonium. Our mean NH₃:CO emission ratio measured near San Francisco (0.031 ppbv/ppbv) and Los Angeles (0.027 ppbv/ppbv) is consistent with SoCAB NH₃:CO emission ratios. Although the climate and vehicle compositions are different, the on-road measurements near Princeton, NJ also showed similar NH₃:CO emission ratios (mean value = 0.029 ppbv/ppbv) compared to the California data.

Figure 7. Distribution of on-road NH₃ EFs measured in all the major urban areas covered during the DISCOVER-AQ campaign in California. Red line shows the log-normal distribution fit with geometric mean of 0.37 g/kg and geometric standard deviation of 0.737.

Figure 8. NH₃:CO emission ratio distributions in this study and NH₃:CO emission ratios measured by aircraft over South Coast Air Basin (SoCAB), CA in 2010. The box-and-whisker plots are defined as in Figure 4. The vertical extension of the green rectangle denotes the reported ±1 standard deviation of the SoCAB measurements, and the black diamond denotes the mean value.

IMPLICATIONS AND FUTURE DIRECTIONS

In 2011, the on-road NH₃ and CO emissions in New Jersey were estimated to be 2.4 Gg/yr and 0.48 Tg/yr, respectively, by the National Emission Inventory (NEI). This gives an NH₃:CO emission ratio of 0.008 ppbv/ppbv, which is substantially smaller than our on-road measurements in New Jersey. The NEI also provides on-road NH₃ and CO emissions in California, which are 16 Gg/yr and 1.7 Tg/yr, respectively. This yields an NH₃:CO emission ratio of 0.018 ppbv/ppbv, also much smaller than our on-road measurements in California. As our on-road CO emission factor measurement also agrees well with recent tunnel measurements and emission models (Supporting Information, Figure S9), this implies that current on-road NH₃ emissions may be significantly underestimated and require further observational constraints. In situ validations of on-road NH₃ emission inventories are limited in the US, and most of them have been conducted in California (see Figure 5). However, few field measurements have been performed in the Northeast/Mid-Atlantic, where traffic and climate conditions are significantly different, and yet on-road emissions are substantial. This study sampled a representative fleet of cars in one specific area in the Northeast, but ultimately more measurements of larger spatial and temporal coverage will be needed.

We demonstrate for the first time in situ, mobile, open-path measurements of NH₃ emissions integrated across vehicles and locations in real-world conditions. Constant EFs based on dynamometer or roadside measurements have been used in NH₃ inventories over large areas. Nevertheless, on-road NH₃ emissions show significant spatial and temporal variations. The motivation of our measurements is to provide real-world observations of EFs over vast spatial coverage and wide range of fleet compositions. Our NH₃ EF measurements, combined with high resolution CO₂ emission inventories, place a stronger constraint on current NH₃ emission inventories.
